Bayesian model description

Let y_i be an indicator of whether individual i tests positive (i.e. equal to 1 if positive, 0 if negative). Furthermore, let π_i denote the probability the individual is seropositive and p_i denote the probability the individual's test outcome is positive, i.e. $\Pr(y_i = 1)$. Given a perfect diagnostic test, $p_i = \pi_i$, however there is non-zero probability of obtaining a false positive and false negative result the test and therefore these quantities are not equal. If se is the true sensitivity and sp is the true specificity of the test, the probabilities are related via

$$p_i = \pi_i * se + (1 - \pi_i) * (1 - sp). \quad (1)$$

Recognizing that seroprevalence may vary by sex and age, we consider the following logistic regression model:

$$\pi_i = \text{logit}^{-1}(\beta_1 + \alpha_{ag[i]}^{ag} + \alpha_{hh[i]}^{hh})$$

where $ag[i]$ indexes which age/gender subpopulation person i belongs, and $hh[i]$ indexes which household person i belongs.

As in Ref. [1], we place a uniform(0,1) prior distribution on the probability that an average person is positive by specifying a unit logistic prior for the intercept β_1 . The effects for age/gender and household have hierarchical priors

$$\alpha_j^{ag} \sim \text{normal}(0, \sigma^{ag})$$

$$\alpha_k^{hh} \sim \text{normal}(0, \sigma^{hh})$$

where σ^{ag} and σ^{hh} are modeled using a $\text{normal}^+(0, 0.5)$.

The model in Eq. (1) requires knowledge of the true sensitivity and specificity of the test, however this is never known in practice. Rather, these test parameters are themselves estimated from data and it is critical the uncertainty in the test characteristics be propagated through to prevalence estimates for accurate inference [2, 1]. We therefore expand our model to include the lab validation data reported by Roche for the Elecsys® Anti-SARS-CoV-2 assay.

Consider n_{se} positive control samples of which y_{se} correctly test positive and n_{sp} negative control samples of which y_{sp} correctly test negative. We model these lab validation results as binomial outcomes:

$$y_{se} \sim \text{binomial}(n_{se}, se),$$

$$y_{sp} \sim \text{binomial}(n_{sp}, sp),$$

and specify uniform(0,1) priors on the sensitivity se and specificity sp parameters.

For the purposes of this study, we considered $n_{se} = 88$, $y_{se} = 81$, $n_{sp} = 5272$, and $y_{sp} = 5262$ using all negative control samples and all positive samples from individuals at least seven days post a positive PCR test [3].

The Bayesian model was fit in R using Stan via the RStan package [4]. The model was fit separately to each area and wave. Posterior mean and 95% equal-tailed credible

intervals were reported for the model parameters based on four chains, each run for 5,000 iterations, with 5,000 iterations of burn-in. The (improved) \hat{R} Markov chain Monte Carlo diagnostic, described in Ref. [5], was less than 1.05 for all parameters, and all effective sample sizes were greater than 5,000. The Stan code for the model was adapted based on that given in Ref. [1] and is provided in full below.

To obtain seroprevalence estimates for entire regions, the age and gender prevalence estimates from the Bayesian model were post-stratified using demographic information specific to each area.

Bayesian model fitting: Stan code
